To some geometric purists this an abuse of terminology, since a polytope is often defined to be a closed, bounded convex set. We are also given a linear polyhedron in $\mathbb{R}^d$, assuming that the inequality relation is $\leq$. Formally, in a point in an $n$-dimensional constrained optimization problem. In constrained optimization, the objective is to find a point in the set of allowable solutions. LP is distinguished by the fact that both the objective function and the constraints are linear.

**Note:** These lecture notes are based on the textbook “Computational Geometry” by Berg et al.; lecture notes from [1]; and lecture notes from MIT 6.854J Advanced Algorithms class by M. Goemans.

## 1 The Linear Programming Problem

In linear programming (LP), we want to find a point in $d$ dimensional space that minimizes a given linear objective function subject to a set of linear constraints. Frequently, LP is done in 100’s or 1,000’s of dimensions, but many applications occur in low-dimensional spaces.

Formally, we’re given a set of linear inequalities, called constraints in $\mathbb{R}^d$. Given a point $(x_1, \ldots, x_d) \in \mathbb{R}^d$, we can express a constraint as $a_1x_1 + \ldots + a_dx_d \leq b$, by specifying coefficients $a_i$, $b \in \mathbb{R}$. Each constraint defines a halfspace in $\mathbb{R}^d$ and the intersection of halfspaces defines a (possibly empty or unbounded) polytope called the feasible polytope.

Next we’re given a linear objective function to be maximized. Given a point $x \in \mathbb{R}^d$, we express the objective function as $c_1x_1 + \ldots + c_dx_d$, for coefficients $c_i$. We can think of the coefficients as a vector $c \in \mathbb{R}^d$, and then the value of the objective function for $x \in \text{Real}^d$ is just $x \cdot c$. Assuming general position, it’s not hard to see that if a solution exists, it’ll be achieved by a vertex of the feasible polytope. See Figure 1.

In general, a $d$-dimensional LP can be expressed as.

Maximize: $c_1x_1 + c_2x_2 + \ldots + c_dx_d$.

Subject to:

$$a_{1,1}x_1 + \ldots + a_{1,d}x_d \leq b_1$$
$$a_{2,1}x_1 + \ldots + a_{2,d}x_d \leq b_2$$
$$\ldots$$
$$a_{n,1}x_1 + \ldots + a_{n,d}x_d \leq b_n$$

---

1. Note that there is no loss in generality by assuming $\leq$ constraints, since we can convert $\geq$ to this form by simply multiplying the inequality by $-1$.

2. Again there is no difference between minimization or maximization since we can negate the coefficients to go from one to the other.
where $x_1, \ldots, x_d$ are the $d$ variables, and $a_{i,j}, c_i$ and $b_i$ are given real numbers. This can be written in matrix notation as

\[
\begin{align*}
\text{Maximize:} & \quad c^T x, \\
\text{Subject to:} & \quad Ax \leq b
\end{align*}
\]

Here $c$ and $x$ are $d$-vectors, $b$ is an $n$ and $A$ is a $n$ by $d$ matrix, where $n$ is the number of constraints. Note that $n$ should be at least as large as $d$.

There are three possible outcomes for a given LP problem. See Figure 2

**Feasible:** An optimal point exists and (assuming general position) is a unique vertex of the feasible polytope.

**InFeasible:** The feasible polytope is empty and there is no solution

**Unbounded:** The feasible polytope is unbounded in the direction of $c$ and so no finite optimal solution exists.

## 2 Solving LP in Constant Dimensions

We now discuss the incremental construction method for efficiently solving LP in constant dimensions. There are other methods for general LP (such as the interior point method). These algorithms have *weakly polynomial time* in that they are polynomial in the number of bits of the input. (This is in contrast to *strongly polynomial time* algorithms that are polynomial in the number of values (i.e. numbers) in the input, not in their size).

Incremental construction is a technique that is frequently used in computational geometry.

### 2.1 Initialization

Recall that we are given $n$ halfspaces $\{h_1, \ldots, h_d\}$ in $\mathbb{R}^d$, and an objective vector $c$, and we want to compute the vertex of the feasible polytope that is the most extreme in the direction of $c$.

We will initially assume that the LP is bounded and that we have $d$ halfspaces that provide us with an initial feasible point. Our approach will be to add halfspaces one at a time and successively update this feasible point.

Finding a set of initial $d$ bounding halfplanes is non-trivial. Assume that there is some maximum value $M$ that any variable can take on. The we add $d$ constraints of the following form for all variables:

$$1 \leq i \leq d \quad x_i \leq M \text{ if } c_i > 0, \quad \text{and} \quad -x_i \leq M \text{ otherwise.}$$

These will be our initial $d$ constraints. Later we will show how to also handle unbounded LPs. See Figure 3 left.
Note that if one of these “max value” constraints turns out to intersect the point that is eventually output, then we know that the original LP is unbounded. In this way, we can detect unbounded LPs also.

Additionally, we’ll assume that there is a unique solution, which we call the optimal vertex. This follows via the general position assumption (or by rotating the plane slightly).

### 2.2 Incremental Algorithm

We can imagine adding the halfspaces \( h_{d+1}, h_{d+2}, \ldots \) and with each addition, update the current optimum vertex if necessary. Note that the feasible polytope gets smaller with each halfplane addition and so the value of the objective function can only decrease. In Figure 4, the \( y \)-coordinate of the feasible vertex decreases.

Let \( v_i \) be the current optimum vertex after halfplane \( h_i \) is added. There are two cases that can occur when \( h_i \) is added. In the easy case, \( v_{i-1} \) lies in the halfspace \( h_i \), and so already satisfies the constraint. Thus \( v_i = v_{i-1} \).

In the hard case, \( v_{i-1} \) is not in the halfplane \( h_i \), i.e. it violates the constraint. In this case, the following lemma shows that \( v_i \) must lie on the hyperplane that bounds \( h_i \).

**Lemma 1.** After addition of halfplane \( h_i \), if the LP is still feasible but \( v_i \neq v_{i-1} \), then \( v_i \) lies on the hyperplane bounding \( h_i \).

**Proof:** Let \( \ell_i \) denote the bounding hyperplane for \( h_i \). By way of contradiction, suppose \( v_i \) does not lie on \( \ell_i \) (see Figure 3). Now consider the line segment between \( v_{i-1} \) and \( v_i \). First note that this line segment must cross \( \ell_i \) since \( v_i \) is in \( h_i \) and \( v_{i-1} \) is not. Further, the entire segment is in the region bounded by the first \( i-1 \) hyperplanes, and so by convexity, the part of the segment that is in \( h_i \) is in the region bounded by the first \( i \) hyperplanes.

Next, note that the objective function is maximized on this line segment at the point \( v_{i-1} \). Also, since the objective function is linear, it must be non-decreasing as we move from \( v_i \) to \( v_{i-1} \). Thus, there is a point on \( \ell_i \) with objective function at least equal to \( v_i \). But this contradicts the uniqueness property, so \( v_i \) must be on \( \ell_i \). \( \square \)

### 2.3 Recursively updating \( v_i \)

Consider the case where \( v_{i-1} \) does not lie in \( h_i \) (Figure 4, left). Again, let \( \ell_i \) denote the hyperplane bounding \( h_i \). We basically project everything onto that hyperplane and solve a \( d-1 \) dimensional LP. In particular, we first project \( c \) onto \( \ell_i \) to get the vector \( c' \) (Figure 4, right). Next intersect each of the halfspaces \( h_1, \ldots h_{i-1} \) with \( \ell_i \). Each projection in a \( d-1 \) dimensional halfspace that lies on \( \ell_i \). Finally, since \( \ell_i \) is a \( d-1 \) dimensional hyperplane, we can project \( \ell_i \) onto \( \mathbb{R}^{d-1} \) with a
1-to-1 mapping. Then we apply this mapping to all the other vectors to get a LP in $\mathbb{R}^{d-1}$ with $i - 1$ constraints.

Algebraically, the way we can do this is simply to set the constraint associated with $\ell_i$ to equality and then remove a variable and a constraint from the LP. For example, if the constraint associated with $\ell_i$ is $x_1 + 2x_2 - 3x_3 \leq 5$. Then we set $x_1 = 5 - 2x_2 + 3x_3$, do a substitution in the LP using this equation wherever we see the variable $x_1$ and then remove the variable $x_1$ from the LP. We can do all this in $O(di)$ time.

### 2.4 Base Case

The recursion ends when we get an LP in 1-dimensional space. Then the projected objective vector just points one way or the other on the real line; the intersection of each half-space with $\ell_i$ is a ray. Computing the intersection of a collection of rays on the line can be done in linear time. (This is the heavy solid line in Figure 4, right). The new optimum is whichever endpoint of this interval is most extreme in the direction of $c'$. If the interval is empty, then the feasible polytope is also empty. So when $d = 1$, we can solve the LP over $i$ halfplanes in $O(i)$ time.

### 2.5 Worst-Case Analysis

Let $T(d, n)$ be the runtime for the LP with $n$ constraints in $d$ dimensional space. For simplicity, we will analyze the recursive algorithm where we remove a constraint, recursively solve the LP, and then either return the recursive solution or project onto the constraint. Then we get the following analysis.

What is $T(d, n)$? If $x_{n-1}$ satisfies the removed constraint (which takes $O(d)$ time to check), we’re done. If not, we reduce the LP to only $d - 1$ variables in $O(dn)$ time ($O(d)$ time to eliminate the variable in each constraint). So, in the worst case, we get

$$T(d, n) = T(d, n - 1) + O(dn) + T(d - 1, n - 1)$$

Unfortunately, the solution to this recurrence is $\Theta(n^d)$.

### 2.6 Randomization to the Rescue

Note that the above analysis assumes we always require a projection, and that we never get the lucky case where $v_{i-1}$ is in $h_i$. If we first randomly permute the hyperplanes, we can calculate the probability of the “lucky” and “unlucky” cases to get an expected runtime. Let $p_i$ be the probability that there is no change to $v_{i-1}$. Then the expected runtime is given by the recurrence relation:
Eliminating the Dependence on Dimension: $n$ vs. $m$ of dimension) such that

Because the geometric series

to either

inscribed. Since all of the

where the constant

Fig. 45: Backwards analysis for the randomized LP algorithm.

Figure 5. Backwards analysis for Randomized LP

\[ T(d, n) = T(d, n-1) + O(d) + p_i(O(dn) + T(d-1, n-1)) \]

So what is $p_i$? Assuming general position, there are exactly $d$ halfspaces whose intersection defines the point $v_i$. At step $i$, there have been $i$ total halfspaces inserted, exactly $d$ of which define the point $v_i$. Since the halfspaces are randomly permuted, this means

\[ p_i = \frac{d}{i} \]

For example, in Figure 5, $h_7$ and $h_4$ define the point $v_i$, so $v_i$ changes if one of these two is the last of the 7 halfspaces inserted. Note that in this analysis, we have denoted $d$ halfspaces as special (those that define $v_i$) and only then revealed the permutation order of the first $i$ halfspaces. This technique is sometimes called backwards analysis or principle of deferred decision.

Plugging $p_i$ back into the recurrence, we now get:

\[ T(d, n) = T(d, n-1) + \frac{d}{n}T(d-1, n-1) + O(d^2) \]

with base cases $T(1, n) = O(n)$ and $T(d, 1) = O(d)$. We can now prove the following.

**Lemma 2.**

\[ T(d, n) = O \left( \sum_{1 \leq i \leq d} \frac{i^2}{i!} \right) d! n = O(d! n) \]

**Proof:** The base case is clear. For simplicity, assume the constant in the asymptotic notation is 1. Then, for the inductive hypotheses, we have that

\[ T(d, n-1) \leq \left( \sum_{1 \leq i \leq d} \frac{i^2}{i!} \right) d!(n-1) \]

and

\[ T(d-1, n-1) \leq \left( \sum_{1 \leq i \leq (d-1)} \frac{i^2}{i!} \right) (d-1)!(n-1) \]
So we can write
\[
T(n, d) \leq \sum_{1 \leq i \leq d} \frac{i^2}{i!} \cdot d!(n-1) + \frac{d}{n} \sum_{1 \leq i \leq (d-1)} \frac{i^2}{i!} \cdot (d-1)!(n-1) + d^2
\]
\[
\leq \left( \sum_{1 \leq i \leq d} \frac{i^2}{i!} \right) d!n
\]
where the first step holds by the IH, and the second holds when \((n-1) + (n-1)/n \leq n\)

\[\square\]

3 Higher Dimension Convex Hull Algorithms

*Note: These lecture notes are based on lecture notes from MIT 6.854J Advanced Algorithms class by M. Goemans*

3.1 Definitions

We assume all points are in *general position*: any \(d + 1\) points do not lie on the same hyperplane.

A *polytope* is informally a geometric object with “flat” sides. More formally, it is the convex hull of a finite number of points. Another recursive definition is:

- A 0-polytope is a point
- A 1-polytope is a line segment (edge)

- The sides (faces) of a \(k\)-polytope are \((k-1)\)-polytopes that may have \((k-2)\)-polytopes in common. (For example a 2-polytope has sides that are line segments, which may meet at points.

A *simplex* is \(k\)-polytope that is the convex hull of its \(k + 1\) vertices. Informally, it is the generalization of the idea of a triangle or tetrahedron.

For any \(0 \leq k < d\), a \(k\)-face of a \(d\)-polytope, \(P\) is a face of \(P\) with dimension \(k\). A \((d-1)\)-face is called a facet. A \((d-2)\)-face is called a ridge. A 1-face is an edge, and a 0-face is a vertex.

A *simplicial polytope* is a polytope where every face is a simplex.

Every facet of a \(d\)-polytope has a *supporting hyperplane*, which is the hyperplane in dimension \(d\) that intersects the entire facet.

3.2 Number of Facets

Even outputting a convex hull in high dimensions can be a challenge. In particular, the number of facets is exponential in the dimension.

Claim: Number of facets of \(P\) is \(O(n^{\lfloor d/2 \rfloor})\)

Proof of this is on page 143 of:

http://www.cs.umd.edu/class/fall2016/cmsc754/Lects/cmsc754-fall16-lects.pdf

This bound is tight. A cyclic polytope has \(\Omega(n^{\lfloor d/2 \rfloor})\) facets.
3.3 Output of convex-hull algorithm

Note that the convex hull in $d$ dimensions will be a simplicial polytope. (Since the points are in general position, each facet is a simplex, the intersections of facets are simplices, etc.).

Thus, the convex hull algorithm outputs a facet graph, $\mathcal{F}(P)$:

- Vertices of $\mathcal{F}(P)$ are the facets of $\text{conv}(P)$ (each vertex is associated with $d+1$ points that define the facet)
- Edges of $\mathcal{F}(P)$ are the ridges of $\text{conv}(P)$, which connect two facets (whose intersection is the ridge.)

An example facet graph is give in Figure 6.

4 An algorithm

This is Seidel’s algorithm which has runtime $O(n+n^{[d/2]})$. For $d \geq 3$, it is optimal. Take a random permutation $x_1,x_2,\ldots,x_n$ of the points Let $P_i$ be the convex hull of $x_1,\ldots,x_i$. We incrementally compute $P_{d+2},\ldots,P_n$, using notions of visibility.

4.1 Visibility

We make use of the following definitions about visibility.

- A facet $F$ is visible from a point $x$, if the supporting hyperplane of $F$ separates $x$ from $P$. Otherwise $F$ is called obscured.
- From the vantage of a point $x$, a ridge of $P$ is called
  - visible: if both facets it connects are visible
  - obscured: if both facets are obscured
  - a horizon ridge: if one facet is visible and the other obscured.

The algorithm is incremental, keeping track of the convex hull of points $x_1,\ldots,x_{i-1}$. It adds vertex $x_i$ in step $i$, removing all facets visible from $x_i$ and adding in all the new facets induced by $x_i$. See Figure 7.
4.2 Seidel’s algorithm

First, randomly permutes all the points in $P$. Then, start out with the convex hull formed by the first $d$ points. Let $C_{i-1}$ be the convex hull of points $p_1, \ldots, p_{i-1}$. All ridges in the current hull are maintained in a search tree, with each ridge having doubly-linked pointers to the two facets forming that ridge. The search tree for the ridges is height $O(d)$, enabling lookups and insertions in $O(d)$ time. The algorithm adds points $x_{d+1}, \ldots, x_n$ as follows.

1. Find one facet $F$ of $C_{i-1}$ that is visible from $x_i$. If there is no visible facet, skip all steps below. A visible facet can be found via linear programming in $O(d!i)$ time as follows. We want to find a hyperplane $a^T x = b$ (where unknowns are $a, b \in \mathbb{R}^d$) such that $a^T x_i = b$ and either (1) $a^T x_j \leq b$ for all $j = 1, \ldots, i-1$; or (2) $a^T x_j \geq b$ for all $j = 1, \ldots, i-1$. This can be found by a linear program in $O(d)$ dimensions, with $O(i)$ constraints. Any solution to this LP will correspond to a hyperplane supporting a new facet in $C_i$ and a horizon ridge. (Vertices in the facet can be found by finding the $d$ points on the hyperplane in $O(di)$ time; all incident ridges in $O(d)$ time). One of the two facets incident to the horizon ridge is a visible facet.

2. Find all visible facets. Determine all horizon ridges. Delete all visible facets and all visible ridges. Can do this via depth first search since visible facets and invisible facets are separated by horizon ridges. (Charge deletion time of facets to when they were created.)

3. Construct all new facets. Each horizon ridge corresponds to a new facet combining $x_i$ and the points in the ridge.
4. Each new facet contains $d$ ridges. Find each ridge in the ridge search tree, or insert if new. Keep pointers back to appropriate new facets in order to match each ridge to the two facets that neighbor it.

### 4.3 Example for Step 1

The equation $(2,1)^T (x, y) = (3, 4)$ defines a line in $\mathbb{R}^2$. In general, $a^T (x, y) = b$ defines a line in $\mathbb{R}^2$. In Step 1, we want to find a vector $a$ and a vector $b$ to ensure that the point $x_i$ is on the line, and that all other points $x_1, \ldots, x_{i-1}$ are on the same side of the halfspace. For example, if $i = 3$ and $x_1 = (1, 0)$, $x_2 = (0, 1)$, and $x_2 = (1, 2)$, we want to solve the following linear program:

Find variables $a_1, a_2, b_1, b_2$, such that:

\[
\begin{align*}
(a_1, a_2)^T (1, 2) &= (b_1, b_2) \\
(a_1, a_2)^T (1, 0) &\leq (b_1, b_2) \\
(a_1, a_2)^T (0, 1) &\leq (b_1, b_2)
\end{align*}
\]

Note that technically, each of these lines expands to two linear inequalities. Also, there is nothing to maximize or minimize, we just want to find any feasible point (which is easier than a usual LP). Finally, we also can check feasibility for a LP where the last two lines have $\geq$ instead of $\leq$.

### 4.4 Runtime

We assume $d$ is a constant. We claim that the time to add point $x_i$ is $O(i + N_i)$ where $N_i$ is a random variable giving the number of new facets created at step $i$. To see this, first note that step (1) takes $O(d!i)$ time to solve the linear program this is $O(i)$ time assuming $d$ is fixed. In step 2, we delete all visible facets and ridges, but the time to do this is charged to when they were created. In step 3, we create $N_i$ new facets, taking time $O(N_i)$. In step 4, there are at most $O(d \cdot N_i)$ new ridges, each of these can be processed in the ridge tree in $O(d)$ time, so this step takes $O(d^2 N_i)$ time. So the total time to process $x_i$ is $O(i + N_i)$.

(Digression: There are $d$ ridges bordering each facet, assuming general position. To see this, note that each facet is determined by $d$ points. And each ridge bordering that facet has $d - 1$ points. This implies that each facet borders $d$ ridges. For example, if we have the facet $(v_1, v_5, v_7, v_8, v_9)$. Then this facet borders the 5 ridges: $(v_5, v_7, v_8, v_9)$; $(v_1, v_5, v_7, v_9)$; $(v_1, v_5, v_7, v_9)$; $(v_1, v_5, v_7, v_9)$; $(v_1, v_5, v_7, v_8)$.)

To get the expected runtime, we can compute $E(N_i)$ using the principle of deferred decision (aka backward analysis). Recall our claim that if we have a polytope with $i$ points in $\mathbb{R}^d$, then the number of facets is $O(i^{d/2})$. First, we fix one of the $O(i^{d/2})$ facets of $C_i$ (see Section 5 for how we can show there are at most $O(i^{d/2})$ facets). The probability that the $i$-th point ($x_i$) participates in this facet is $d/i$.

Hence using linearity of expectation over all $O(i^{d/2})$ facets, we can say that $E(N_i) = O(\frac{d}{i} i^{d/2}) = O(i^{d/2})$. Thus, the expected runtime of Seidel’s algorithm is:

\[
\sum_{i=1}^{n} O(i + N_i) = \sum_{i=1}^{n} O(i + i^{(d/2)-1}) = O(n^{(d/2)})
\]
5 Bounding the Number of Facets

5.1 Polarity

There are two ways to create polytopes: (1) convex hull of a set of points; and (2) intersection of a collection of closed halfspaces. We show that these are essentially identical through a concept called polar transformation. A polar transformation maps points to hyperplanes and vice versa. This transformation is another example of duality.

Fix any point \( O \) in \( d \)-dimensional space. \( O \) can be the origin, and then we can view any point \( p \in \mathbb{R}^d \) as a \( d \)-element vector. (If \( O \) is not the origin then \( p \) can be identified with the vector \( p - O \).) Given two vectors \( p \) and \( x \), recall that \( p \cdot x \) is the dot-product of \( p \) and \( x \). Then the polar hyperplane of \( p \) is denoted:

\[
p^* = \{ x \in \mathbb{R}^d, \ p \cdot x = 1 \}.
\]

Clearly this is linear in the coordinates of \( x \), and so \( p^* \) is a hyperplane in \( \mathbb{R}^d \). If \( p \) is on the unit sphere centered at \( O \), then \( p^* \) is a hyperplane that passes through \( p \) and is orthogonal to the vector \( \overrightarrow{Op} \).

As \( p \) moves away from the origin along this vector, the dual hyperplane move closer to the origin, and vice versa, so that the product of their distances from the origin is always 1. See Figure 8(a).

5.2 Properties

Like with point-line duality, the polar transformation satisfies certain incidence and inclusion properties between points and hyperplanes. For example, let \( h \) be any hyperplane that does not contain \( O \). The pole of \( h \), denoted \( h^* \), is the point that satisfies \( h^* \cdot x = 1 \) for all \( x \in h \).

Let \( p \) be any point in \( \mathbb{R}^d \) and let \( h \) be any hyperplane in \( \mathbb{R}^d \). The polar transformation satisfies the following properties. For a hyperplane \( h \), let \( h^+ \) be the halfspace containing the origin and \( h^- \) be the other halfspace for \( h \). See Figure 8(b).
Simple and Simplicial Polytopes:

- **Incidence Preserving**: Point $p$ belongs to hyperplane $h$ iff $h^*$ belongs to $p^*$
- **Inclusion Reversing**: Point $p$ belongs to halfspace $h^+$ iff point $h^*$ belongs to halfspace $(p^*)^+$. This implies that point $p$ belongs to halfspace $h^-$ iff point $h^*$ belongs to halfspace $(p^*)^-$. Intuitively, this means that the polarity transform reverses relative positions.

Note that a bijective transformation that preserves incidence relations is called a duality. So the above claim shows that the polarity transform is another duality.

### 5.3 Convex Hulls and Halfspace Intersection

We now want to transform a polytope defined as the convex hull of a finite set of points to a polytope defined as the intersection of a finite set of closed halfspaces. To do this, we need a mapping from a point to a halfspace. For any point $p \in \mathbb{R}^d$, define

$$p^\# = (p^*)^* = \{x \in \mathbb{R}^d \mid x \cdot p \leq 1\}$$

This just first finds the polar hyperplane of $p$, and then takes the closed halfspace containing the origin.

Now for any set of points $P \subseteq \mathbb{R}^d$, define its polar image to be the intersection of these halfspaces.

$$P^\# = \{x \in \mathbb{R}^d \mid x \cdot p \leq 1, \forall p \in P\}$$

Thus, $P^\#$ is the intersection of a finite set of closed halfspaces, one for each $p \in P$. Is $P^\#$ convex? [Jared: discuss in lecture]

The following lemma shows that $P$ and $P^\#$ are essentially equivalent via polarity.

**Lemma 3.** Let $S = \{p_1, \ldots, p_n\}$ be a set of points in $\mathbb{R}^d$ and let $P = \text{conv}(S)$. Then:

$$P^\# = S^\#$$

Furthermore:

1. A point $a \in \mathbb{R}^d$ is on the boundary of $P$ iff the hyperplane $a^*$ supports $P^\#$.
2. Each $k$-face of $P$ corresponds to a $(d - 1 - k)$-face of $P^\#$.
Proof: Assume that $O$ is contained within $P$. We can guarantee this by, e.g., translating $P$ so that its center of mass coincides with the origin.

Consider some point $v_1 \in P$ that is on some hyperplane $h$ supported by a facet containing points $v_1, v_2, \ldots, v_d \in P$. Then, hyperplanes $v_1^*, \ldots, v_d^*$ contain point $h^*$ in the polar plane, by the incidence preservation property. This shows parts (1) and (2) of the lemma.

Now consider some point $v \in S - P$, i.e. point $v$ is inside $\text{conv}(S)$, and consider all the hyperplanes $h_1, \ldots, h_\ell$ that support the facets of $\text{conv}(S)$. Note that $v \in h_i^+$ for all $i = 1, \ldots, \ell$. Then, hyperplane $v^*$ does not in intersect any of the points $h_1^*, \ldots, h_\ell^*$, and each of these points $h_i^*$ is in the open halfspace $h_i^+$ by the inclusion reversing property. This shows that $P^\# = S^\#$ in the polar plane. (See Figure 9 for an example with the point $d$ that is in $S$ but not in $P$. Note that $d^*$ is a redundant halfspace in the intersection of planes in the polar space.)

Thus, the polar image $P^\#$ of a polytope is structurally isomorphic to $P$. Also the convex hull problem is equivalent to the halfspace intersection problem. In fact, once we have the incidence graph output from one of the problems, we can just flip that graph upside down to get the output of the other problem.

As an aside, note that we can talk about polytopes being polar duals of each other. For example, the square and the octahedron are polar duals; the dodecahedron and icosohedron are polar duals, and the tetrahedron is self-dual.

5.4 How Many Facets?

So, how many facets are in a convex hull defined by $n$ points in $d$ dimensional space? Recall that a simplex, or simplicial polytope, is a polytope where each $j$-face is the intersection of exactly $d - j$-hyperplanes. It is not hard to see that simplicial polytopes maximize the number of faces for a given set of vertices and maximize the number of vertices for a given set of halfplanes.

The following theorem has a remarkably beautiful proof due to Raimund Seidel that uses polar duality.

**Theorem 1.** A polytope in $\mathbb{R}^d$ that is the convex hull of $n$ points has $O(n^{\lfloor d/2 \rfloor})$ facets. A polytope in $\mathbb{R}^d$ that is the intersection of $n$ halfspaces has $O(n^{\lfloor d/2 \rfloor})$ vertices.

Proof: We will prove the polar form of the theorem. Consider a polytope by intersection of $n$ halfspaces in general position. Suppose by convention that $x_d$ is the vertical axis. Then given a face, its highest and lowest vertices are defined as those having the maximum and minimum $x_d$ coordinates, respectively. (Note that there are no ties, assuming general position). The proof is
based on a charging argument. We place a charge at each vertex. We then move the charge at each vertex to a specially chosen incident face so that no face receives more than 2 charges.

Consider some vertex \( v \). Note that there are exactly \( d \) edges (1-faces) that are incident to \( v \) (See Figure 10 for example in \( \mathbb{R}^5 \)). Consider a horizontal (i.e. orthogonal to \( x_d \)) hyperplane that passes through \( v \). Note that at least \( \lfloor d/2 \rfloor \) of the edges must lie on the same side of this hyperplane (by general position, no edges are on the hyperplane).

Hence there is a face of dimension at least \( \lfloor d/2 \rfloor \) that spans these edges and is incident to \( v \) (i.e. the 3-face above \( v \) in Figure 10). So \( v \) is either the highest or lowest vertex on this face. We assign \( v \)'s charge to this face. Thus, we charge every vertex to a face of dimension at least \( \lfloor d/2 \rfloor \), and every such face will be charged twice.

So how many faces have been charged? A simple bound on the number of \( j \)-faces is \( \binom{n}{d-j} \). This holds since each \( j \) face is the intersection of some subset of \( d-j \) of the \( n \) hyperplanes. Thus, the total number of vertices is

\[
2 \sum_{j=[d/2]}^{d} \binom{n}{d-j} = 2 \sum_{k=0}^{\lfloor d/2 \rfloor} \binom{n}{k} \sum_{k=0}^{\lfloor d/2 \rfloor} O(n^k) = O(n^{\lfloor d/2 \rfloor})
\]

In the above inequalities, the first line holds by a change of the index of summation. The second line holds by noting that \( \binom{n}{k} = O(n^k) \) and the last line holds by noting that a geometric summation is \( O() \) of its largest summand.

Is this bound tight? Yes. There is a family of polytopes called cyclic polytopes which match this asymptotic bound.
